# Effective Synthesis of Optimal Controllers Using Bisimulations <sup>1</sup>

Mireille Broucke<sup>2</sup> Maria D. DiBenedetto<sup>3</sup> Stefano Di Gennaro<sup>4</sup> Alberto Sangiovanni-Vincentelli<sup>5</sup>

## Abstract

We consider the synthesis of optimal controls for continuous feedback systems by recasting the problem to a hybrid optimal control problem: to synthesize optimal enabling conditions for switching between locations in which the control is constant. We provide a single-pass algorithm to solve the dynamic programming problem that arises, with added constraints to ensure non-Zeno trajectories.

## 1 Introduction

In this paper we continue our investigation of the application of hybrid systems and bisimulation to optimal control problems. In the first paper [3] we developed a discrete method for solving an optimal control problem based on hybrid systems and bisimulation. We showed that the value function of the discrete problem converges to the value function of the continuous problem as a discretization parameter  $\delta$  tends to zero. In this paper we focus on the pragmatic question of how the discretized problem can be efficiently solved.

Following the introduction of the concept of viscosity solution [5], Capuzzo-Dolcetta [4] introduced a method for obtaining approximations of viscosity solutions based on time discretization of the Hamilton-Jacobi-Bellman (HJB) equation. The approximations of the value function correspond to a discrete time optimal control problem, for which an optimal control can be synthesized that is piecewise constant. Finite difference approximations were also introduced in [6] and [10]. In general, the time discretized approximation of the HJB equation is solved by finite element methods. Gonzales and Rofman [9] introduced a discrete approximation by triangulating the domain of the

finite horizon problem they considered, while the admissible control set is approximated by a finite set. Gonzales and Rofman's approach is adapted in several papers, including [8]. The approach of [11] uses the special structure of an optimal control problem to obtain a single-pass algorithm to solve the discrete problem. thus bypassing the expensive iterations of a finite element method. The essential property needed to find a single pass algorithm is to obtain a partition of the domain so that the cost-to-go value from any equivalence class of the partition is determined from knowledge of the cost-to-go from those equivalence classes with strictly smaller cost-to-go values. In this paper we obtain a partition of the domain provided by a bisimulation partition. The combination of the structure of the bisimulation partition and the requirement of non-Zeno trajectories enables us reproduce the essential property of [11], so that we obtain a Dijkstra-like algorithmic solution. Our approach has complexity  $O(N \log N)$  if suitable data structures are used, where N is the number of locations of the finite automaton.

While the objective is to solve a continuous optimal control problem, the method can be adapted to solve directly the problem of optimal synthesis of enabling conditions for hybrid systems. In that spirit, [1] investigates games on timed automata and obtains a dynamic programming formulation as well.

# 2 Optimal control problem

cl(A) denotes the closure of set A.  $\|\cdot\|$  denotes the Euclidean norm.  $\mathcal{X}(\mathbb{R}^n)$  denotes the sets of smooth vector fields on  $\mathbb{R}^n$ .  $\phi_t(x_0, \mu)$  denotes the trajectory of  $\dot{x} = f(x, \mu)$  starting from  $x_0$  and using control  $\mu(\cdot)$ .

Let U be a compact subset of  $\mathbb{R}^m$ ,  $\Omega$  an open, bounded, connected subset of  $\mathbb{R}^n$ , and  $\Omega_f$  a compact subset of  $\Omega$ . Define  $\mathcal{U}_m$  to be the set of measurable functions mapping [0,T] to U. We define the minimum hitting time  $T:\mathbb{R}^n\times\mathcal{U}_m\to\mathbb{R}^+$  by  $T(x,\mu)=\infty$  if  $\{t|\phi_t(x,\mu)\in\Omega_f\}$  otherwise. A control  $\mu\in\mathcal{U}_m$  specified on [0,T] is admissible for  $x\in\Omega$  if  $\phi_t(x,\mu)\in\Omega$  for all  $t\in[0,T]$ . The set of admissible controls for x is denoted  $\mathcal{U}_x$ . Let  $\mathcal{R}:=\{x\in\Omega\mid\exists\mu\in\mathcal{U}_x.\ T(x,\mu)<\infty\}$ . We consider

the following optimal control problem. Given  $y \in \Omega$ ,

$$\label{eq:minimize} \begin{array}{ll} \mbox{minimize} & J(y,\mu) = \int_0^{T(y,\mu)} L(x(s),\mu(s)) ds \\ & + h(x(T(y,\mu))) \end{array} \tag{1}$$

subject to 
$$\dot{x} = f(x, \mu)$$
, a.e.  $t \in [0, T(y, \mu)]$  (2)

$$x(0) = y \tag{3}$$

among all admissible controls  $\mu \in \mathcal{U}_y$ .  $J: \mathbb{R}^n \times \mathcal{U}_m \to \mathbb{R}$  is the cost-to-go function,  $h: \mathbb{R}^n \to \mathbb{R}$  is the terminal cost, and  $L: \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}$  is the instantaneous cost. At  $T(y,\mu)$  the terminal cost  $h(x(T(y,\mu)))$  is incurred and the dynamics are stopped. The control objective is to reach  $\Omega_f$  from  $y \in \Omega$  with minimum cost.

The value function or optimal cost-to-go function  $V: \mathbb{R}^n \to \mathbb{R}$  is given by  $V(y) = \inf_{\mu \in \mathcal{U}_y} J(y, \mu)$  for  $y \in \Omega \setminus \Omega_f$ , and by V(y) = h(y) for  $y \in \Omega_f$ . V satisfies the Hamilton-Jacobi-Bellman equation

$$-\inf_{u \in U} \left\{ L(x, u) + \frac{\partial V}{\partial x} f(x, u) \right\} = 0 \tag{4}$$

at each point of  $\mathcal{R}$  at which it is differentiable. The HJB equation is an infinitesimal version of the equivalent  $Dynamic\ Programming\ Principle\ (DPP)$  which says that

$$V(x) = \inf_{\mu \in \mathcal{U}_x} \left\{ \int_0^t L(\phi_s(x,\mu), \mu(s)) ds + V(\phi_t(x,\mu)) \right\},$$

for  $x \in \Omega \setminus \Omega_f$  and V(x) = h(x) for  $x \in \Omega_f$ , assuming a small-time controllability condition holds. Viscosity solutions [5] provide the unique solution of (4) without assuming differentiability. We showed in [3] that under assumptions of Lipschitz continuity of f, L, and h, and non-Zenoness and transversality with  $\Omega_f$  of  $\epsilon$ -optimal trajectories, that a particular discrete approximation  $\hat{V}$  of the value function converges to the viscosity solution of HJB.

## 3 From hybrid automata to finite automata

In [3] we proposed a mapping from the continuous optimal control problem (1)-(3) to a hybrid optimal control problem. The first step is to restrict the class of controls over which the cost function is minimized to piecewise constant controls taking values in a set  $\Sigma_{\delta} \subseteq U$ .  $\Sigma_{\delta} \subseteq U$  is a finite approximation of U having a mesh size  $\delta := \sup_{u \in U} \min_{\sigma \in \Sigma_{\delta}} \|u - \sigma\|$ . Next we restrict the continuous behavior to the set of vector fields  $\{f(x,\sigma)\}_{\sigma \in \Sigma_{\delta}}$ . If we associate each vector field to a location of a hybrid automaton and, additionally, define a location reserved for when the target is reached, we obtain a hybrid automaton  $H := (\Sigma \times \mathbb{R}^n, \Sigma_{\delta}, D, E_h, G, R)$  which has the following components:

State set  $\Sigma \times \mathbb{R}^n$  is a finite set  $\Sigma = \Sigma_{\delta} \cup \{\sigma_f\}$  of control locations and n continuous variables  $x \in$ 

 $\mathbb{R}^n$ .  $\sigma_f$  is a terminal location when the continuous dynamics are stopped (in the same sense that the dynamics are stopped in the continuous optimal control problem).

**Events**  $\Sigma_{\delta}$  is a finite set of control event labels.

**Vector fields**  $D: \Sigma \to \mathcal{X}(\mathbb{R}^n)$  is a function assigning an autonomous vector field to each location; namely  $D(\sigma) = f(x, \sigma)$ .

Control switches  $E_h \subset \Sigma \times \Sigma$  is a set of control switches.  $e = (\sigma, \sigma')$  is a directed edge between a source location  $\sigma$  and a target location  $\sigma'$ . If  $E_h(\sigma)$  denotes the set of edges that can be enabled at  $\sigma \in \Sigma$ , then  $E_h(\sigma) := \{(\sigma, \sigma') \mid \sigma' \in \Sigma \setminus \sigma\}$  for  $\sigma \in \Sigma_\delta$  and  $E_h(\sigma_f) = \emptyset$ . Thus, from a source location not equal to  $\sigma_f$ , there is an edge to every other location (but not itself), while location  $\sigma_f$  has no outgoing edges.

Enabling conditions  $G: E_h \to \{g_e\}_{e \in E_h}$  is a function assigning to each edge e an enabling (or guard) condition  $g_e \subset \mathbb{R}^n$ .

The enabling conditions are unknown and must be synthesized algorithmically. (See [3] for how the enabling conditions are extracted once the discrete problem is solved.) Trajectories of H evolve in  $\sigma$ -steps and t-steps.  $\sigma$ -steps occur when H changes locations (and the control changes value, since there are no self-loops) and t-steps occur when the continuous state evolves according to the dynamics of a location as time passes. The reader is referred to [3] for precise statements. A hybrid trajectory is non-Zeno if between every two non-zero duration t-steps there are a finite number of  $\sigma$ -steps and zero duration t-steps.

Let  $\lambda$  represent an arbitrary time interval. A bisimulation of H is an equivalence relation  $\simeq \subset (\Sigma_{\delta} \times \mathbb{R}^n) \times$  $(\Sigma_{\delta} \times \mathbb{R}^n)$  such that for all states  $p_1, p_2 \in \Sigma_{\delta} \times \mathbb{R}^n$ , if  $p_1 \simeq p_2$  and  $\sigma \in \Sigma_{\delta} \cup \{\lambda\}$ , then if  $p_1 \stackrel{\sigma}{\to} p'_1$ , there exists  $p'_2$  such that  $p_2 \stackrel{\sigma}{\to} p'_2$  and  $p'_1 \simeq p'_2$ . One sees that  $\simeq$  encodes  $\sigma$ -steps and t-steps of H in a time abstract form by partitioning  $\Sigma_{\delta} \times \mathbb{R}^n$ . If  $\simeq$  has a finite number of equivalence classes, then they form the states of a finite automaton A. If  $q := [(\sigma, x)]$  and  $q' := [(\sigma', x')]$ are two different equivalence classes of  $\simeq$ , then A has an edge  $q \to q'$  if there exists  $(\sigma, y) \in q$  and  $(\sigma', y') \in q'$ such that  $(\sigma, y) \to (\sigma', y')$  is a  $\sigma$ -step or t-step of H. We define the set of interesting equivalence classes of  $\simeq$ , denoted Q, as those that intersect  $\Sigma_{\delta} \times cl(\Omega)$ , and we identify a distinguished point  $(\sigma, \xi) \in q$  for each  $q \in Q$ , denoted  $q = [(\sigma, \xi)]$ .

Consider the non-deterministic automata with cost structure  $A=(Q,\Sigma_{\delta},E,obs,Q_f,\hat{L},\hat{h}).$  Q is the state set just defined, and  $\Sigma_{\delta}$  is the set of control labels as before.  $obs: E \to \Sigma_{\delta}$  is a map that assigns a control label to each edge and is given by  $obs(e) = \sigma'$ , where  $e=(q,q'), q=[(\sigma,\xi)]$  and  $q'=[(\sigma',\xi')].$   $Q_f$  is an over

(or under) approximation of  $\Omega_f$ ,  $Q_f = \{q \in Q \mid \exists x \in \Omega_f : (\sigma, x) \in q \}$ .  $E \subseteq Q \times Q$  is the transition relation of A and is defined assuming that each enabling condition is initially the entire region  $\Omega$ . The identity map on control switches is implemented in A by an over-approximation in terms of equivalence classes of  $\simeq$ . That is, for  $\sigma \neq \sigma'$ ,  $[(\sigma, x)]$ ,  $[(\sigma', x')]$ )  $\in E$  if the projections to  $\mathbb{R}^n$  of  $[(\sigma, x)]$  and  $[(\sigma', x')]$  have non-empty intersection. This over-approximation introduces non-determinacy in A. Let

$$\tau_q = \sup_{(\sigma,x),(\sigma,y)\in q} \{ t \mid y = \phi_t(x,\sigma) \}.$$

Let e = (q, q') with  $q = [(\sigma, \xi)]$  and  $q' = [(\sigma', \xi')]$ .  $\hat{L}: E \to \mathbb{R}$  is the discrete instantaneous cost given by

$$\hat{L}(e) := \begin{cases} \tau_q L(\xi, \sigma) & \text{if } \sigma = \sigma' \\ 0 & \text{if } \sigma \neq \sigma'. \end{cases}$$
 (5)

 $\hat{h}: Q \to \mathbb{R}$  is the discrete terminal cost given by  $\hat{h}(q) :=$  $h(\xi)$ . A transition or step of A from  $q \in Q$  to  $q' \in Q$ with observation  $\sigma' \in \Sigma_{\delta}$  is denoted  $q \stackrel{\sigma'}{\to} q'$ . If  $\sigma \neq \sigma'$ the transition is referred to as a control switch, and it is forced.  $\sigma = \sigma'$  the transition is referred to as a time step. If E(q) is the set of edges that can be enabled from  $q \in Q$ , then for  $\sigma \in \Sigma_{\delta}$ ,  $E_{\sigma}(q) = \{e \in E(q) \mid obs(e) =$  $\sigma$ . If  $|E_{\sigma}(q)| > 1$ , then we say that  $e \in E_{\sigma}(q)$  is unobservable in the sense that when control event  $\sigma$  is issued, it is unknown which edge among  $E_{\sigma}(q)$  is taken. (Note that unobservability of edges refers strictly to the discrete automaton A, whereas in H one may be able to reconstruct which edge was taken using continuous state information). If  $\sigma = \sigma'$ , then  $|E_{\sigma}(q)| = 1$ , by the uniqueness of solutions of ODE's and by the definition of bisimulation.

A control policy  $c:Q\to \Sigma_\delta$  is a map assigning a control event to each state;  $c(q)=\sigma$  is the control event issued when the state is at q. A trajectory  $\pi$  of A over c is a sequence  $\pi=q_0\stackrel{\sigma_1}{\to}q_1\stackrel{\sigma_2}{\to}q_2\stackrel{\sigma_3}{\to}\dots$ ,  $q_i\in Q$ . Let  $\Pi_c(q)$  be the set of trajectories starting at q and applying control policy c, and let  $\tilde{\Pi}_c(q)$  be the set of trajectories starting at q, applying control policy c, and eventually reaching  $Q_f$ . If for every  $q\in Q$ ,  $\pi\in\Pi_c(q)$  is non-Zeno then we say c is an admissible control policy. The set of all admissible control policies for A is denoted C. A control policy c is said to have a loop if A has a trajectory  $q_0\stackrel{c(q_0)}{\to}q_1\stackrel{c(q_1)}{\to}\dots\stackrel{c(q_{m-1})}{\to}q_m=q_0,\ q_i\in Q$ . A control policy has a Zeno loop if it has a loop made up of control switches and/or zero duration time steps (i.e.  $\tau_q=0$ ) only.

**Lemma 1** A control policy c for non-deterministic automaton A is admissible if and only if it has no Zeno loops.

**Proof:** First we show that a non-deterministic automaton with non-Zeno trajectories has a control policy without Zeno loops. For suppose not. Then a trajectory starting on a state belonging to the loop can

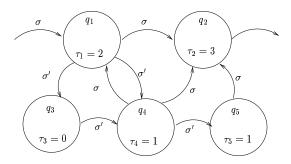

Figure 1: Fragment of automaton with a zero duration time step.

take infinitely many steps around the loop before taking a non-zero duration time step. This trajectory is not non-Zeno, a contradiction. Second, we show that a control policy without Zeno loops implies non-Zeno trajectories. Suppose not. Consider a Zeno trajectory that takes an infinite number of control switches and/or zero duration time steps between two non-zero duration time steps. Because there are a finite number of states in Q, by the Dirichlet Principle, one of the states must be repeated in the sequence of states visited during the control switches and/or zero duration time steps. This implies the existence of a loop in the control policy. Either each step of the loop is a control switch, implying a Zeno loop; or the loop has one or more zero duration time steps. But the bisimulation partition permits zero duration time steps only if  $\tau_q = 0$ , which implies a Zeno

**Example 1** Consider the automaton in Figure 1. Suppose that we define a control policy  $c(q_1) = \sigma'$ ,  $c(q_3) = \sigma'$ ,  $c(q_4) = \sigma$ , and  $c(q_5) = \sigma$ . Starting at  $q_1$  two possible trajectories are  $q_1 \stackrel{\sigma'}{\to} q_3 \stackrel{\sigma'}{\to} q_4 \stackrel{\sigma}{\to} q_2$ , or  $q_1 \stackrel{\sigma'}{\to} q_3 \stackrel{\sigma'}{\to} q_4 \stackrel{\sigma}{\to} q_1$ . The first trajectory has a zero duration time step. The control is inadmissible since the second trajectory has a Zeno loop.

## 4 Dynamic programming

In this section we formulate the dynamic programming problem on A. This involves defining a cost-to-go function and a value function that minimizes it over control policies suitable for non-deterministic automata.

Let  $\pi = q_0 \xrightarrow{\sigma_1} q_1 \dots q_{N-1} \xrightarrow{\sigma_N} q_N$ , where  $q_i = [(\sigma_i, \xi_i)]$  and  $\pi$  takes the sequence of edges  $e_1 e_2 \dots e_N$ . We define a discrete cost-to-go  $\hat{J}: Q \times \mathcal{C} \to \mathbb{R}$  by

$$\hat{J}(q,c) = \max_{\pi \in \hat{\Pi}_c(q)} \left\{ \sum_{j=1}^{N_{\pi}} \hat{L}(e_j) + \hat{h}(q_{N_{\pi}}) \right\}$$

if  $\Pi_c(q)=\tilde{\Pi}_c(q)$  and  $\hat{J}(q,c)=\infty$  otherwise, where  $N_\pi=\min\{j\geq 0\mid q_j\in Q_f\}.$  We take the maximum

over  $\tilde{\Pi}_c(q)$  because of the non-determinacy of A: it is uncertain which among the (multiple) trajectories allowed by c will be taken so we must assume the worst-case situation. The discrete value function  $\hat{V}:Q\to\mathbb{R}$  is

$$\hat{V}(q) = \min_{c \in \mathcal{C}} \hat{J}(q, c)$$

for  $q \in Q \setminus Q_f$  and  $\hat{V}(q) = \hat{h}(q)$  for  $q \in Q_f$ . We showed in [3] that  $\hat{V}$  satisfies a DPP that takes into account the non-determinacy of A and ensures that optimal control policies are admissible. Let  $\mathcal{A}_q$  be the set of control assignments  $c(q) \in \Sigma_{\delta}$  at q such that c is admissible.

# Proposition 1 $\hat{V}$ satisfies

$$\hat{V}(q) = \min_{c(q) \in \mathcal{A}_q} \left\{ \max_{e = (q, q') \in E_{\sigma'}(q)} \{ \hat{L}(e) + \hat{V}(q') \} \right\}$$
 (6)

for  $q \in Q \setminus Q_f$  and  $\hat{V}(q) = \hat{h}(q)$  for  $q \in Q_f$ .

# 5 Non-deterministic Dijkstra algorithm

The dynamic programming solution (6) can be viewed as a shortest path problem on a non-deterministic graph subject to all optimal paths satisfying a non-Zeno condition. We propose an algorithm which is a modification of the Dijkstra algorithm for deterministic graphs [7].  $F_n$  is the set of states that have been assigned a control and are deemed "finished" at iteration n, while  $U_n$  are the unfinished states. At each n,  $Q = U_n \cup F_n$ .  $\Sigma_n(q) \subseteq \Sigma_\delta$  is the set of control events at iteration n that take state q to finished states exclusively.  $U_n$  is the set of states for which there exists a control event that can take them to finished states exclusively.  $V_n(q)$  is a tentative cost-to-go value at iteration n.  $B_n$  is the set of "best" states among  $\tilde{U}_n$ . It is assumed in the following description that initially  $\hat{V}(q) = \infty$  and  $c(q) = \emptyset$  for all  $q \in Q$ .

Procedure NDD: 
$$\begin{split} F_1 &= Q_f; \ \text{In } q \in Q_f, \\ \text{for each } q \in Q_f, \ \hat{V}(q) = \hat{h}(q); \\ \text{for n } = 1 \text{ to N, do} \\ \text{for each } q \in U_n, \\ &\sum_n(q) = \left\{\sigma' \in \Sigma_\delta \mid \text{if } q \xrightarrow{\sigma'} q', \text{then } q' \in F_n\right\}; \\ \tilde{U}_n &= \left\{q \in U_n \mid \Sigma_n(q) \neq \emptyset\right\}; \\ \text{for each } q \in \tilde{U}_n, \\ \tilde{V}_n(q) &= \min_{\sigma' \in \Sigma_n(q)} \{ \max_{e = (q,q') \in E_{\sigma'}(q)} \{ \hat{L}(e) + \hat{V}(q') \} \}; \\ B_n &= \text{argmin}_{q \in \tilde{U}_n} \{ \hat{V}_n(q) \}; \\ \text{for each } q \in B_n, \\ &\hat{V}(q) = \tilde{V}_n(q); \\ &c(q) &= \text{argmin}_{\sigma' \in \Sigma_n(q)} \{ \text{max}_{e = (q,q') \in E_{\sigma'}(q)} \{ \hat{L}(e) + \hat{V}(q') \} \}; \\ \text{endfor} \\ &F_{n+1} = F_n \cup B_n; \ U_{n+1} = Q - F_{n+1}; \end{split}$$

We observe a few properties of the algorithm. First, if all states of Q can reach  $Q_f$  then  $Q-Q_f=\cup_n B_n$ . Second, as in the deterministic case, the algorithm computes  $\hat{V}$  in order of level sets of  $\hat{V}$ . In particular,  $\hat{V}(B_n) \leq \hat{V}(B_{n+1})$ . Finally, we need the following property.

**Lemma 2** For all  $q \in Q$  and  $\sigma' \in \Sigma_{\delta}$ ,

$$\hat{V}(q) \leq \max_{e = (q,q') \in E_{\sigma'}(q)} \{ \hat{L}(e) + \hat{V}(q') \}.$$

**Proof:** Fix  $q \in Q$  and  $\sigma' \in \Sigma_{\delta}$ . There are two cases. Case 1.

$$\hat{V}(q) \le \max_{e=(q,q')\in E_{\sigma'}(q)} {\{\hat{V}(q')\}}.$$

In this case the result is obvious. Case 2.

$$\hat{V}(q) > \max_{e=(q,q')\in E} \{\hat{V}(q')\}. \tag{7}$$

We observed above that q belongs to some  $B_n$ . Suppose w.l.o.g. that  $q \in B_j$ . Together with (7) this implies  $q' \in F_j$  for all q' such that  $q \stackrel{\sigma'}{\to} q'$ . This, in turn, means that  $\sigma' \in \Sigma_j(q)$  and according to the algorithm

$$\hat{V}(q) = \tilde{V}_j(q) \le \max_{e = (q, q') \in E_{\sigma'}(q)} \{\hat{L}(e) + \hat{V}(q')\}$$

which proves the result.

**Theorem 1** Algorithm NDD is optimal and synthesizes a control policy with no Zeno loops.

**Proof:** First we prove optimality. Let V(q) be the optimal (best worst-case) cost-to-go for  $q \in Q$  and  $\overline{Q} = \{q \in Q \mid V(q) < \hat{V}(q)\}$ . Let  $l(\pi_q)$  be the number of edges taken by the shortest optimal (best worst-case) trajectory  $\pi_q$  from q. Define  $\overline{q} = \arg\min_{q \in \overline{Q}} \{l(\pi_q)\}$ . Suppose that the best worst-case trajectory starting at  $\overline{q}$  is  $\pi_{\overline{q}} = \overline{q} \stackrel{\sigma'}{\to} \overline{\overline{q}} \to \dots$  We showed in the previous lemma that

$$\hat{V}(\overline{q}) \le \max_{e = (\overline{q}, q') \in E_{\sigma'}(\overline{q})} \{\hat{L}(e) + \hat{V}(q')\} \le \hat{L}(e) + \hat{V}(\overline{\overline{q}}).$$

Since  $\pi_{\overline{q}}$  is the best worst-case trajectory from  $\overline{q}$  and by the optimality of  $V(\overline{q})$ 

$$V(\overline{q}) = \max_{e = (\overline{q}, q') \in E_{\sigma'}(\overline{q})} \{ \hat{L}(e) + V(q') \} = \hat{L}(e) + \hat{V}(\overline{\overline{q}}).$$

Since  $\pi_{\overline{q}}$  is the shortest best worst-case trajectory, we know that  $\overline{\overline{q}} \notin \overline{Q}$ , so  $V(\overline{\overline{q}}) = \hat{V}(\overline{\overline{q}})$ . This implies  $\hat{V}(\overline{q}) \leq \hat{L}(e) + V(\overline{\overline{q}}) = V(\overline{\overline{q}})$ , a contradiction.

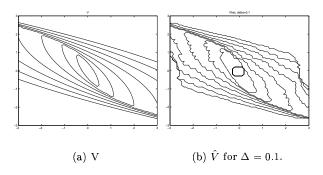

Figure 2: Continuous and discrete value functions for double integrator

To prove that the algorithm synthesizes a policy with no Zeno loops we argue by induction. The claim is obviously true for  $F_1$ . Suppose that the states of  $F_n$  have been assigned controls forming no Zeno loops. Consider  $F_{n+1}$ . Each state of  $B_n$  takes either a time step or a control switch to  $F_n$  so there cannot be a Zeno loop in  $B_n$ . The only possibility is for some  $q \in B_n$  to close a Zeno loop with states in  $F_n$ . This implies there exists a control assignment that allows an edge from  $F_n$  to q to be taken; but this is not allowed by NDD. Thus,  $F_{n+1}$  has no Zeno loops.

# 6 Example

We apply our method to the time optimal control problem of a double integrator

$$\begin{array}{rcl} \dot{x}_1 & = & x_2 \\ \dot{x}_2 & = & u_1 \end{array}$$

Given the set of admissible controls  $U=\{u:|u|\leq 1\}$ , we select  $\Omega=(-1,1)\times(-1,1)$  and  $\Omega_f=\overline{B}_\epsilon(0)$ , the closed epsilon ball centered at 0. The cost-to-go function is  $J(x,\mu)=\int_0^{T(x,\mu)}dt$ . The bang-bang solution obtained using Pontryagin's maximum principle is well known to involve a single switching curve. The continuous value function V is shown in Figure 2(a).

To construct the hybrid automaton H we select  $\Sigma_{\delta} = \{-1,1\}$ . H is show in Figure 3. The state space is  $\{\sigma_{-1} = -1, \sigma_1 = 1, \sigma_f\} \times \mathbb{R}^n$ .  $g_{e_{-1}}$  and  $g_{e_1}$  are unknown and must be synthesized, while  $g_{e_2} = g_{e_3} = \Omega_f$ . A first integral for vector field  $\dot{x}_1 = x_2, \ \dot{x}_2 = 1$  is  $x_1 - \frac{1}{2}x_2^2 = c_1, \ c_1 \in \mathbb{R}$ . For  $\dot{x}_1 = x_2, \ \dot{x}_2 = -1$  a first integral is  $x_1 + \frac{1}{2}x_2^2 = c_2, \ c_2 \in \mathbb{R}$ . We select a transverse foliation (see [2]) for each vector field, given by  $x_2 = c_3$ . We define  $Q, Q_f, E, \hat{L}$  and  $\hat{h}$  for automaton A derived from H in Figure 3. Q can be visualized using Figure 4.

The states  $q \in Q$  are of the form  $(\sigma, [x])$  with  $\sigma \in \{\sigma_{-1}, \sigma_1\}$ . For the case  $\sigma = \sigma_1$  with  $c_1, c_2 \in \mathbb{R}$ , [x]

**Figure 4:** Partitions for states  $\sigma_1$  and  $\sigma_{-1}$  of the hybrid automaton of Figure 3

is either an open subset of  $\mathbb{R}^2$  bounded by the leaves  $c_1 < x_1 - \frac{1}{2}x_2^2 < c_1 + \Delta$  and  $c_2 < x_2 < c_2 + \Delta$ ; or an open interval in a horizontal leaf  $x_1 - \frac{1}{2}x_2^2 = c_1$ ,  $c_2 < x_2 < c_2 + \Delta$ ; or an open interval in a vertical leaf  $c_1 < x_1 - \frac{1}{2}x_2^2 < c_1 + \Delta$ ,  $x_2 = c_2$ ; or a point  $x_1 - \frac{1}{2}x_2^2 = c_1$ ,  $x_2 = c_2$ . Analogous expressions can be written for  $\sigma = \sigma_{-1}$ . In Figure 4,  $\Delta = 0.25$ ,  $c_1 \in [-1,1]$  and  $c_2 \in [-1,1]$ . If we identify equivalence classes  $(\sigma, [x])$  by their Euclidean coordinates  $(c_1,c_2)$  directly, then  $Q_f$ , shown in Figure 4 as the regions inside the dotted lines, includes states  $(\sigma, [x])$ , where [x] satisfies  $c_1, c_2 \in (-\Delta, \Delta)$ .

Let us consider the edges corresponding to control switches of A.  $q=(\sigma_1,[x])\in Q$  has an outgoing edge to  $q'=(\sigma_{-1},[y])\in Q$  if  $[x]\cap [y]\neq \emptyset$ . For example, for  $q=(\sigma_1,[x])$  and [x] satisfying  $c_1\in (-.25,-.5)$  and  $c_2=.25$ , there are three outgoing edges from q to  $q'_i,i=1,\ldots,3$ , with [y] satisfying  $c_2=.25$  and  $c_1\in (-.5,-.25),\ c_1=-.25,\ and\ c_1\in (-.25,0),\ respectively. Edges corresponding to time steps of <math>A$  are determined from the direction of the flows. For example, for  $q=(\sigma_1,[x])$  with [x] satisfying  $c_1\in (-.25,-.5)$  and  $c_2=.25$ , there is an outgoing edge from q to  $q'=(\sigma_1,[y])$  with [y] satisfying  $c_1\in (-.25,-.5)$  and  $c_2\in (.25,.5)$ .

The results of algorithm NDD are shown in Figure 2(b) and Figure 5. In Figure 5 the dashed line is the

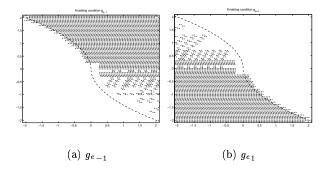

Figure 5: Enabling conditions

smooth switching curve for the continuous problem. The black dots identify equivalence classes where NDD assigns a control switch. Considering  $g_{e_{-1}}$  we see that the boundary of the enabling condition in the upper left corner is a jagged approximation using equivalence classes of the smooth switching curve. Initial conditions in the upper left corner just inside the enabling condition must switch to a control of u = -1, otherwise the trajectory will increase in the  $x_2$  direction and not reach the target. Initial conditions in the upper left corner just outside the enabling condition must allow time to pass until they reach the enabling condition, for if they switched to u = -1 they would be unable to reach the target. Hence the upper left boundary of the enabling condition is crisp. The lower right side of the enabling condition which has islands of time steps shows the effect of the non-determinacy of automaton A. These additional time steps occur because it can be less expensive to take a time step than to incur the cost of the worst case control switch. Notice that all such initial conditions eventually take a control switch. This phenomenon of extra time steps is a function of the mesh size  $\delta$ : as  $\delta$  decreases there are fewer extra time steps. Finally we note that the two enabling conditions have an empty intersection, as expected in order to ensure non-Zeno trajectories.

## 7 Conclusion

We have developed a prototype tool for the synthesis of hybrid optimal controls based on bisimulation. The algorithm has complexity  $O(N\log N)$  where N is the number of states of the automaton. The number of states is exponential in the dimension of the continuous state space. In the "vanilla" version of our approach, the automaton is constructed before running the Dijkstra-like algorithm. To improve the speed and the memory usage of the algorithm, we plan to build the automaton on the fly while algorithm NDD is executing. In addition, we plan to apply the approach to solving a number of optimal control problems arising in automotive engine control.
